(Received 14 December 2016; accepted 1 May 2017)

With increasing performance requirements in power electronics, the necessity has emerged to investigate the thermo-mechanical behavior of thick Cu metallizations (≥5 μm). Cu films on rigid substrates in the range of 5–20 μm were thermally cycled between 170 and 400 °C by a fast laser device. Compared to the initial microstructures, a texture transition toward the {100} out-of-plane orientation with increasing film thickness was observed during thermo-mechanical cycling, along with an abnormal grain growth in the {100}-oriented grains and a gradual development of substructures in a crystallographic arrangement. Compared to the well-studied thin Cu film counterparts (≤5 μm), the surface damage showed a 1/hₚ dependency. Transition from an orientation independent (hₚ = 5 μm) to an orientation specific thermo-mechanical fatigue damage (hₚ = 10, 20 μm) was observed following a higher damage tolerance in {100} oriented grains.

I. INTRODUCTION

Since the large scale production of integrated circuits in the 1960s, thin film materials for microelectronic devices have become a major topic in the modern materials science community. The ongoing performance increase with the number of transistors and switching frequency coupled with the miniaturization of semiconductor components require sophisticated deposition processes and excellent film material properties. In many silicon-based microelectronic devices, increasing power densities lead to significant temperature rises up to ~400 °C within the microsecond regime during switching operations. This results in large thermal stresses due to different coefficients of thermal expansion (CTE) of the materials, where plastic deformation can occur if the yield stress of the metallization is reached. Such a repetitive dynamic temperature rise leads to a thermo-mechanical damage of the metallization in the form of severe surface roughening and voiding. These features can result in local excess temperatures leading to a thermal runaway and local melting of silicon.

To overcome these problems, one key concept of metallization development is to increase the film thickness (hₚ), which leads to a greater specific heat capacity and longer operational lifetime. In a previous study, it has been shown that increasing the copper metallization thickness to 20 μm will result in the largest relative benefit gain such as the maximum peak temperature during a power pulse. Copper, used in modern power semiconductor metallization schemes, exhibits very interesting structural properties. Besides its excellent electrical and thermal properties, copper has a very low stacking fault energy (SFE) resulting in a high number of twin boundaries, as well as a large elastic anisotropy factor. These attributes result in a large variety of initial microstructural characteristics, such as grain size, d, and texture, because they are directly coupled to the corresponding film thickness. In copper films, a pronounced texture transition from a dominating {111} texture at small thickness (<1 μm) to a high fraction of {100}-oriented grains at greater film thickness (5–10 μm) can be observed, as well as a different grain size distribution between the two texture components. These initial microstructural differences in thicker Cu films lead to the presumption that regardless of the chosen fatigue experiment, the microstructural evolution and related fatigue damage in copper films will depend on the particular film thickness.

In the literature, numerous studies report on the (thermo)-mechanical fatigue of copper films in the range of hₚ = 0.1–5 μm on thick substrates. Fatigue damage, which is often described by extrusions/intrusions and severe roughening on the film surface, is directly correlated to film thickness where the height and extrusion density decrease with decreasing
thickness. Other studies attribute localized differences in the fatigue damage to the distinctly different behavior of \{100\} and \{111\} out-of-plane oriented grains. Although mechanisms are not fully understood, authors emphasized that dislocation substructures (e.g., \{100\} walls) being more likely in \{100\}-oriented grains, and the large difference in grain resolved in-plane stress $\sigma$ ($\sigma_{11}/\sigma_{100} \sim 2.3$) due to elastic anisotropy, are potential reasons why film microstructures with a different fraction of \{100\} and \{111\} grains behave differently with respect to fatigue testing.

The question arises as to which thermo-mechanical behavior can be observed when $h_f \geq 5 \, \mu m$, where the fraction of \{100\}-oriented grains is expected to significantly increase. The current literature on Cu foils indicates a lower tensile strength for 20 $\mu m$ foils due to the increase of the soft \{100\} texture component but does not provide results with respect to thermo-mechanical fatigue. Presented here are experimental results of thick thermo-mechanically loaded copper films, ranging from 5 to 20 $\mu m$ thickness and with various initial film textures. The local microstructural evolution, which is based on a site-specific tracking method, in combination with wafer curvature measurements, local scanning electron microscopy (SEM) studies, and surface roughness measurements is used to evaluate the film thickness influence upon thermo-mechanical fatigue.

II. MATERIALS AND EXPERIMENTAL

A. Materials synthesis and preparation

All samples were prepared via sputter and electrochemical deposition. First, a tungsten-based (~100 nm) adhesion layer was sputtered on 725 $\mu m$ thick silicon wafers with a \{100\} orientation, followed by a 300 nm sputtered Cu seed layer. On the top of the seed layer, electrochemical deposition was used and the deposition time was adjusted so that the final copper film thicknesses of 2.5, 5, 10, and 20 $\mu m$ were obtained. The electrolyte was designed to result in an almost impurity-free Cu film. All samples were subjected to a 30 min heat treatment at 400 °C in a reducing atmosphere (forming gas) to establish a stable room temperature microstructure.

B. Experimental techniques

The basic thermo-mechanical characterization of the films was performed using a wafer curvature system for in situ film stress characterization up to 1000 °C. With a multiple optical beam sensor, kSA multibeam optical sensor (MOS) (k-Space Associates, Inc., Dexter, Michigan), the film stress evolution was measured from room temperature to 400 °C using a heating and cooling rate of 10 °C/min.

To experimentally simulate rapid temperature rises comparable to thermo-mechanical loading of the copper metallizations by high power pulses in power electronics, samples with lateral dimensions of 7 $\times$ 7 mm were thermally cycled in a custom-built fast thermal laser cycling device in an reducing atmosphere (forming gas, chamber pressure $\sim 160 \, mbar$). The samples were thermo-mechanically loaded between 170 and 400 °C, resulting in a total applied thermal strain of about 0.7% per cycle due to the CTE mismatch using the average CTE values for Cu and Si in the corresponding temperature range. One laser cycle corresponds to an average heating rate of 1050 °C/s and a cooling rate of 110 °C/s with a total cycle time of approximately 2 s. For details on the cycling process, see Refs. 15 and 28.

After marking the film surface with Vickers orientation indents, the surface and microstructural evolution within a representative surface area were studied using a Dimension 3100 (Bruker, Inc., Billerica) atomic force microscope (AFM) and a SEM LEO 1525 (Zeiss, Inc., Oberkochen, Germany) with electron backscatter diffraction (EBSD) analysis. For more information about the site-specific evaluation, see Ref. 24. Between thermal cycling, samples were subjected to a selective etch to remove any copper oxide using a 100 vol% acetic acid solution at 35–40 °C for 2–4 min. AFM images were made in the tapping mode and postimage analysis was performed using the Gwyddion 2.45 software. For EBSD investigations, depending on the grain size, the scan size varied from 120 $\times$ 120 to 500 $\times$ 500 $\mu m^2$ with a step size between 0.2 and 0.9 $\mu m$. For all scans, an acceleration voltage of 20 kV and a 120 $\mu m$ aperture size were used and post-EBSD analysis was performed with the TSL Analysis v5 software. SEM micrographs were obtained using the secondary electron mode with a 20 $\mu m$ aperture size and 6 kV acceleration voltage.

III. RESULTS AND DISCUSSION

A. Initial microstructural analysis

The specimens in the as-received state showed a clear film thickness dependence with respect to the initial grain size and texture for $h_f \geq 5 \, \mu m$ (Fig. 1). A randomly oriented polycrystalline grain structure was obtained for $h_f = 2.5$ and 5 $\mu m$ (Figs. 1(a) and 1(b)). With increasing film thickness, a predominant \{100\}-textured was observed for $h_f = 10 \, \mu m$ (Fig. 1(c)) and for $h_f = 20 \, \mu m$ (Fig. 1(d)). For all samples, an average grain orientation map (EBSD image) in this study. The grain size is a function of film thickness (see Table I). An average grain size of 2.5 $\pm$ 0.8 $\mu m$ (including primary twin boundaries) was observed for the thinnest Cu film ($h_f = 2.5 \, \mu m$) and $d$ increased to 17.4 $\pm$ 3.9 $\mu m$ for $h_f = 20 \, \mu m$. The initial \{100\} out-of-plane order
orientation fraction scales linearly with $h_t$ and a significant increase of the grain size (including primary twins) was observed. This is in good agreement with the literature, where driving forces such as the minimization of interfacial energy $\Delta \gamma_i$ and strain energy $\Delta W_e$ explain the increase of the grain size and preferable $\{100\}$ out-of-plane direction, respectively. Observations of the present films indicate that the texture transition does occur at thicknesses greater than $5 \, \mu m$ since the texture appearance [Figs. 1(a) and 1(b)] of the $h_t = 2.5 \, \mu m$ Cu film is almost identical to $h_t = 5 \, \mu m$, which deviates from other studies where the transition thickness was found to lie between 3 and $5 \, \mu m$ and the absolute $\{100\}$ texture strength was different with respect to $h_t$. The $2.5 \, \mu m$ thick film is used here only to illustrate the differences between thin films ($\approx 5 \, \mu m$) and thick films ($\approx 5 \, \mu m$), which is the focus of this paper.

To study the change in texture in a quantitative manner, columnar grains are assumed and the mean elastic modulus is calculated. By taking the elastic constants of the stiffness tensor for copper ($c_{11}: 168.4 \, GPa$, $c_{12}: 121.4 \, GPa$, $c_{44}: 75.4 \, GPa$), the mean elastic modulus as a function of the initial microstructures was calculated using the EBSD information (for detailed information see Ref. 15). As shown in Table I, for $h_t = 2.5$ and $5 \, \mu m$ thick films, the calculated mean elastic modulus is $112 \, GPa$. These two films have an almost randomly oriented microstructure, where an elastic modulus of $109 \, GPa^{15}$ was determined. With film thicknesses greater than $5 \, \mu m$, the average elastic modulus decreases due to the increase of the soft $\{100\}$ out-of-plane texture component.

The basic thermo-mechanical behavior using the stress-temperature evolution [Fig. 1(e)] also varies as a function of film thickness. The biaxial film stress is shown between room temperature and $400 \, ^{\circ}C$ of the first cycle and between $80$ and $400 \, ^{\circ}C$ of the second cycle. Starting with similar tensile film stresses, a maximum compressive stress of $-190 \, MPa$ was observed for $h_t = 2.5 \, \mu m$, which decreases to approximately $120$, $80$, and $60 \, MPa$ for $h_t = 5$, $10$, and $20 \, \mu m$, respectively. In terms of the shape of the film stress hysteresis, an influence of the changing initial film texture was observed. The two random textured microstructures ($h_t = 2.5$ and $5 \, \mu m$) exhibit a very similar thermo-mechanical behavior and a gradual change from elastic to plastic film stress evolution is observed.

For film thicknesses $\approx 5 \, \mu m$, the stress hysteresis changes to a very sharp elastic to plastic film stress behavior, most notably for $h_t = 20 \, \mu m$. It can be seen that two pronounced elastic regions are present for the heating and cooling segments and are followed by plastic flow at an almost constant stress. The transition of the stress-temperature behavior can also be observed in the decrease of the thermoelastic slopes with increasing film thicknesses (Table I). To quantify the correlation of the observed thermo-mechanical behavior with respect to film thickness, the elastic film modulus $E_t$ was

W.C. stands for wafer curvature measurements.
determined in the temperature range of 90–110 °C (second cycle) using
\[
\frac{d\sigma_f}{dT} \sim \frac{\Delta \sigma_f}{\Delta T} = \left[ \frac{E_f}{(1 - \nu_f)} \right] \times (\alpha_s - \alpha_f),
\]
where the differential change of film stress as a function of sample temperature can be seen as the thermoelastic slope \( \Delta \sigma_f/\Delta T \). The corresponding stress slopes are the product of the biaxial modulus of the film, where \( \nu_f \) denotes Poisson’s ratio of the film, and the thermal expansion mismatch between the substrate, \( \alpha_s \), and the film, \( \alpha_f \), in the given temperature range. As shown in Table I, the thermoelastic slopes decreased with increasing \( h_f \). The initial Poisson’s ratios of the films have been calculated (Table I) by calculating Poisson’s ratio for the three main orientations ((111), (110), and (100)) according to Refs. 35 and 36 (via calculating \( M_{(hkl)} \) and \( E_{(hkl)} \)). Corresponding Poisson’s ratios \( (\nu_{(100)} = 0.42, \nu_{(110)} = 0.44, \nu_{(111)} = 0.27) \) were then weighted using the fractional grain areas of the crystal orientations ((111), (110), and (100)) determined using the EBSD images (a maximum orientation tolerance of 8° was used). The remaining texture components were assigned to \( \nu = 0.35 \) which can be attributed to a texture-free copper film.\(^{34} \) As shown in Table I, \( \nu_f \) increases from \( \nu_f = 0.35 \) in the two texture-free films (\( h_f = 2.5 \) and 5 \( \mu \)m) to \( \nu_f = 0.386 \) for the thickest copper film. The trend of Poisson’s ratio with respect to film thickness is quantitatively confirmed by the calculated elastic moduli in the range of 90–110 °C (using a \( \Delta \alpha \) of 14.1 ppm/K\(^{15} \)), where the decrease of \( E_f \) correlates to the \( E \) determined from the EBSD measurements. The overall elastic film behavior relates to an increase of the softer \{100\} texture component for thicknesses between 5 and 20 \( \mu \)m.

In terms of the elastic properties, a good correlation between the wafer curvature and EBSD data was found for films thicker than 5 \( \mu \)m, considering that Cu has a temperature coefficient of elastic modulus of about \(-245 \) ppm/°C.\(^{34} \) However, for the 2.5 \( \mu \)m Cu film, a rather large discrepancy of the elastic modulus values (Table I) was found indicating that in thinner films (\( \leq 5 \) \( \mu \)m) other mechanisms overlap with the elastic response. It appears that the thermoelastic response for thin Cu films is inversely proportional to the film thickness and does not directly correlate to the initial elastic properties based on the microstructure and texture. The same behavior as the 2.5 \( \mu \)m film was also reported in another study where the thermo-elastic slope for 1 \( \mu \)m thin Cu films was found to be 3.6 MPa/K (in comparison, 2.88 MPa/K for 2.5 \( \mu \)m).\(^{37} \)

It was also observed that the stress relaxation behavior changed with increasing \( h_f \). While the two thinner Cu films (2.5 and 5 \( \mu \)m) showed distinct stress relaxation after reaching the maximum compressive film stress, the 20 \( \mu \)m thick Cu film illustrated plastic flow at an almost constant stress level of around \(-60 \) MPa/35 MPa. Such a thermo-mechanical behavior is often referred as Al-type (e.g., passivated films).\(^{38} \) where a thermally activated (stress driven) dislocation glide was proposed as the dominant deformation mechanism.\(^3 \) Cu-type curves, for example, the stress-temperature behavior of the \( h_f = 2.5 \) \( \mu \)m, use creep mechanisms such as power law breakdown or diffusional creep, which involve atomic diffusion.\(^{39} \) Considering that diffusion paths such as grain boundaries and twins were found to scale inversely proportional with \( h_f \) the obtained results by wafer curvature would indicate a gradual change from a Cu-type to an Al-type with increasing \( h_f \).

B. Global microstructure evolution

Since a large increase of the \{100\} out-of-plane texture component as well as different thermo-mechanical behavior can be observed with Cu film thicknesses \( \geq 5 \) \( \mu \)m, samples with \( h_f = 5, 10, \) and 20 \( \mu \)m were thermo-mechanically cycled up to 1000 cycles with the fast thermal laser cycling device. In Fig. 2, the global microstructural parameters of the three samples are shown as a function of cycle number. Figure 2(a) indicates that a significant grain growth occurs during thermal cycling in the three Cu films. In all three samples, the increase of the grain size (including twins) was the largest during the first 50 cycles followed by a constant increase up to 1000 thermal cycles. The grain size increased from \( 3.4 \pm 1.1 \) \( \mu \)m up to \( 9.5 \pm 2.8 \) \( \mu \)m (\( h_f = 5 \) \( \mu \)m), from \( 6.1 \pm 1.7 \) \( \mu \)m up to \( 29.1 \pm 6.1 \) \( \mu \)m (\( h_f = 10 \) \( \mu \)m), and from \( 17.3 \pm 3.9 \) \( \mu \)m up to \( 79.5 \pm 14.1 \) \( \mu \)m (\( h_f = 20 \) \( \mu \)m).

Figure 2(b) presents the fractional area of the \{100\} texture evolution as a function of thermal cycles. A similar steady (linear) texture increase for all three film thicknesses is seen, where the area fraction for \( h_f = 5 \) \( \mu \)m increased from 5 up to 22%, for \( h_f = 10 \) \( \mu \)m from around 17 up to 39%, and for \( h_f = 20 \) \( \mu \)m the values increased from 40 up to 60%. As a result of the prominent \{100\} texture development, the average elastic moduli [Fig. 2(c)], including linear fit lines] of all specimens decrease during thermo-mechanical cycling. The thinnest Cu film with \( h_f = 5 \) \( \mu \)m shows a decrease of the mean elastic modulus from 112 GPA to 98 GPA, while the thicker films \( h_f = 10 \) and 20 \( \mu \)m exhibit a decrease from 100 GPA to 82 GPA and from 84 GPA to 74 GPA, respectively.

To again quantitatively compare the three film thicknesses from an energetic point of view, a columnar grain structure is assumed. The biaxial strain, \( M \), generated during cycling leads to different elastic strain energy densities, \( W \), in the Cu films because the strain energy is orientation dependent in the elastic regime and described by\(^{40} \)
Using the elastic moduli from Fig. 2(c), the calculated initial biaxial moduli of $M_{5\mu m}$, $M_{10\mu m}$, and $M_{20\mu m}$ are 172 GPa, 157 GPa, and 137 GPa, respectively, can be determined. After 1000 thermal cycles, the respective biaxial moduli were lowered to 154 GPa, 131 GPa, and 122 GPa, for 5, 10, and 20 $\mu m$ film thickness, respectively. The as-received data from the 2.5 $\mu m$ thick film are used as a reference because it exhibits an almost random texture. The minimization of elastic strain energy can be calculated by

$$W = M_{hi}e^2.$$

Using the elastic moduli from Fig. 2(c), the calculated initial biaxial moduli of $M_{5\mu m}$, $M_{10\mu m}$, and $M_{20\mu m}$ are 172 GPa, 157 GPa, and 137 GPa, respectively, can be determined. After 1000 thermal cycles, the respective biaxial moduli were lowered to 154 GPa, 131 GPa, and 122 GPa, for 5, 10, and 20 $\mu m$ film thickness, respectively. The as-received data from the 2.5 $\mu m$ thick film are used as a reference because it exhibits an almost random texture. The minimization of elastic strain energy can be calculated by

$$\Delta W = (M_{2.5\mu m} - M_{hi})e^2.$$

Applying Eq. (3) leads to a reduction of the elastic strain energy after 1000 cycles of about $18 \times e^2$, $41 \times e^2$, and $50 \times e^2$ GJ/m$^3$, compared to a randomly oriented polycrystalline film, for $h_i = 5$, 10, and 20 $\mu m$, respectively. The reduction of the elastic strain energy emphasizes the dominant effect of the {100} out-of-plane grain growth. Considering that the {100} orientation has a $M_{100} = 115$ GPa, biaxial moduli calculated from the obtained EBSD analysis [Fig. 2(c)] reveal a transition from an elastically anisotropic microstructure to an isotropic structure with increasing film thickness and cycling stage.

The evolution of the fractional (primary) twin boundary and high angle grain boundary (HAGB) lengths are both presented in Fig. 2(d), where the total measured boundary length is divided by the total scan area. This results in a quantitative parameter with respect to twin migration as a dominant plastic deformation mechanism, as well as indicating energy minimizing processes related to grain boundary energy. The fractional twin boundary length for $h_t = 5 \mu m$ decreases from 0.94 to 0.30 $\mu m^{-1}$, for $h_t = 10 \mu m$ from 0.63 to 0.16 $\mu m^{-1}$, and for $h_t = 20 \mu m$ from 0.30 to 0.06 $\mu m^{-1}$. With respect to the fractional HAGB length evolution, a reduction from 0.45 to 0.24 $\mu m^{-1}$, from 0.29 to 0.10 $\mu m^{-1}$, and from 0.17 to 0.05 $\mu m^{-1}$ for $h_t = 5, 10$, and 20 $\mu m$ was obtained, respectively.

The presented results in Fig. 2(d) indicate a faster rate of interface energy minimization with increasing $h_t$. For $h_t = 5 \mu m$ the grain boundary length per unit area decreased to less than half of its initial value, while for $h_t = 20 \mu m$ the HAGB was reduced by more than a factor of three. This leads to the conclusion that the minimization of $\gamma_1$ is proportional to $h_t$.

The texture evolution of the three films is presented in Fig. 3 with inverse pole figures (IPFs). The color code indicates the likelihood of the appearance of certain crystal orientations compared to a random orientation (blue/dark blue color). From the initial texture, it can be observed that with increasing film thickness the texture exhibits a gradual transition from a randomly oriented texture to a {100} dominated texture. During the cycling a texture increase of the {100} out-of-plane orientation, along with a slight increase of its {212} twin
configuration, in all three film thicknesses occurs. The 
\{110\} plane orientation vanishes for all three thicknesses. 
After 1000 thermal cycles, only the \{100\} orientation 
with its corresponding \{212\}-oriented twin, a texture 
component close to the \{311\} orientation and the \{111\} 
out-of-plane orientation, is present where the fraction is 
significantly reduced with increasing film thickness. 
From Fig. 3 it appears that the \{311\} orientation develops 
due to a constant grain rotation and will be discussed in 
Sec. IV.

C. Local microstructure evolution

Many studies have already presented detailed work 
on the thermo-mechanical behavior of thinner films 
(\leq 5 \, \mu m).\textsuperscript{11,13,17,28} Here, microstructural observations 
are presented for the 20 \, \mu m thick film to emphasize the 
effect of film thickness, grain size, and texture on the 
thermo-mechanical behavior. In Fig. 4 the microstructural 
changes of the first 50 thermal cycles are presented for 
the same area using EBSD and AFM. The initial 
microstructure of the 20 \, \mu m film [Figs. 4(a)–4(c)] 
consists of many twinned grains (white lines indicate 
the HAGB and black lines indicate primary twins), where 
a significant portion has a \{100\} orientation in the normal 
direction (ND) to the film plane [Fig. 4(a)], but different 
in-plane orientations, as shown by the EBSD image 
showing the transversal direction [Fig. 4(b)]. Most of 
the grains exhibit pronounced grain boundaries, which 
can be seen in the AFM image [Fig. 4(c)]. After 50 
cycles, significant changes in the microstructure can be 
seen by comparing the initial [Figs. 4(a) and 4(b)] to the
after cycling grain orientation maps [Figs. 4(d) and 4(e)]. A group of grains with different out-of-plane and in-plane orientations collectively deform by shear, resulting in a crystallographic segment with an approximate \{321\} out-of-plane orientation, indicated by Feature 1. The \{321\} oriented segment is in a primary twin boundary relation with other growing grains (Feature 2). After 50 cycles, the newly formed twin segment [Figs. 4(e) and 4(f), Feature 1] and the surrounding grains have the same in-plane orientation [Fig. 4(e)]. From Fig. 4(f) it can be observed that the initial grain boundaries are still present and severe shear of the grains occurred on different glide planes. Furthermore, new HAGB interfaces are observed [Fig. 4(f), white arrows]. These findings suggest that grains in thicker films first reorient to compensate for the in-plane misorientation when a biaxial strain is applied and a collective reorientation of the former small grains occurs.

Figure 5 presents the microstructural changes for $h_t = 20 \ \mu m$ after 250, 500, and 1000 cycles [Figs. 5(a)–5(c)]. The microstructure of the selected area after the first 250 thermal cycles [Figs. 5(a) and 5(d)] is composed of a majority of large \{100\} out-of-plane oriented grains with their corresponding \{212\} oriented primary twins and smaller twinned grains with different orientations (see the highlighted rectangular section). Continued thermal-mechanical cycling resulted in a pronounced growth of \{100\}-oriented grains, causing large areas with the same crystallographic orientation (see Feature 1). The formation of crystal segments with low angle grain boundaries (LAGB) in the large \{100\}-oriented grains can be observed during the cycling. Additionally, kernel average misorientation images are provided [Figs. 5(d)–5(f)]. A local misorientation value of the kernel is assigned (2nd neighbor) with respect to the center of the kernel to indicate subgrain structures, such as LAGB, $\theta \leq 15^\circ$, and plastic strain accumulation. The substructures, indicated by sharp green lines in the kernel average misorientation plots [Figs. 5(d)–5(f)], exhibit local misorientation angles of about six to twelve degrees. The circular features [Figs. 5(c) and 5(f)] highlight the geometric substructures with approximate angles of about 90, 135, and 150° between the straight LAGB domains. As seen from the grain orientation maps and kernel
average misorientation plots, Feature 2 does not change the size despite the plastic strain accumulation during cycling. Grains and twins with an orientation other than \{100\} either significantly shrink or accumulate plastic strain during the thermal cycling. Such a behavior can be seen in the highlighted rectangular section where grains do not greatly change in the size but accumulate plastic strain during cycling. This is qualitatively indicated by the color changes [Fig. 5(c)] and the formation of a dense network of local misorientations [Figs. 5(d)–5(f)] in this area.

The experimental results indicate that the mechanisms behind the grain growth during thermo-mechanical cycling are strongly influenced by \(h_f\) and texture. The pronounced grain growth in the early stage (Fig. 4) was accomplished by collective shearing across the initial grains where it appears that the in-plane crystal orientation plays an important role. Experimental evidence is found in Fig. 5, where the same twin (marked as Feature 2) is preserved throughout the cycling experiment. The grain growth of the \{100\} texture component in the 20 \(\mu m\) thick film follows the development of defined grain substructures (circular features), while grains with other orientations have severe plastic strain accumulation. In a recent work, the authors found a similar behavior for a 5 \(\mu m\) thick Cu film cycled in an infrared furnace where such geometric substructures formed gradually from an initial misorientation gradient in an approximately \{100\}-oriented grain. The \{100\}-specific subgrain structures were also previously observed by others in thermally cycled submicron thick copper lines, where angles of 5–10° misorientation developed.

FIG. 5. Microstructural evolution of \(h_f = 20 \mu m\) illustrated by site-specific grain orientation maps with IQ analysis between 250, 500, and 1000 cycles (a–c). The corresponding kernel average misorientation plots are presented (d–f). Scale bar is valid for all micrographs.
microscope (TEM) studies of mechanically fatigued copper films revealed that a grain size/film thickness dependent dislocation structure develops in \{100\} out-of-plane oriented grains. Geometric arrays of \{100\}-aligned dislocation walls form in larger grains due to the promotion of dislocation activity in larger crystals. Studies on the characterization of dipolar dislocation walls could be used to explain the geometry of the incurred LAGB substructures in the abnormally large \{100\} oriented grain. The authors\textsuperscript{44,45} conclude that fatigue experiments in face centered cubic (fcc) metals, especially in crystals with a \{100\} crystal orientation suitable for multiple slip, would result in \{100\} and \{110\} walls. The model of combined (double) slip on the perpendicular to the dislocation walls, was used to explain the resulting arrays of edge dislocations.\textsuperscript{44}

D. Microstructural damage analysis

To qualitatively assess the thermo-mechanical fatigue damage, Fig. 6 presents representative areas after 1000 cycles of \(h_i = 5–20 \mu m\) using SEM and EBSD micrographs. For the 5 \(\mu m\) thick Cu film [Figs. 6(a) and 6(b)], surface damage is present over the entire area. For example, pronounced glide bands formed within grains at twin boundary interfaces (Feature 1) and severe roughening can be observed at the HAGB (white lines) where hillock-like formations (Feature 2) at the grain boundaries are observed. The area in the circular marking is an example of extrusions/intrusions within individual grains.

With increasing film thickness, the surface damage changes. In the presented area for \(h_i = 10 \mu m\) [Figs. 6(c) and 6(d)], large \{100\}-oriented grains exhibit pronounced shearing (slip) at their twin boundary interfaces after 1000 thermal cycles (Feature 3). Damage evolution differs depending on the grain orientation. For example, at Feature 4, the approximately \{212\}-oriented twin segment has severe surface roughening along preferred slip planes [Fig. 6(e)], while in the \{100\}-oriented twin counterparts the same fatigue features are not seen. Grains with an orientation other than \{100\} exhibited severe shearing at their twin planes and have a rougher appearing surface (Feature 5). Plasticity in the soft oriented \{100\} grains appears to accumulate differently than in other oriented crystal segments. The color gradients in Feature 6 [Fig. 6(d)] indicate a gradual change of orientation. The observation is that a gradual change in orientation across \{100\}-grains (constant tilt with respect to ND) occurs as a result of stress field minimizing LAGB.\textsuperscript{46} This suggests that dislocation reactions are involved in the crystal rotation which are energetically preferred compared to those that would result in glide steps at the film surface. In contrast to grains with orientations other than \{100\}, there was no dominant slip system activated that would lead to the formation of one specific slip pattern at the film surface.

For the Cu film thickness \(h_i = 20 \mu m\), it can be seen that thermo-mechanical fatigue damage strongly depends on the out-of-plane orientation. Feature 7 [Figs. 6(e) and 6(f)] shows that no significant surface damage is present in the \{100\}-oriented grains. Grains with crystal orientations other than \{100\} show severe surface roughening in the form of slip traces (Feature 8). The approximate \{311\} oriented grain and its twin show pronounced slip steps at the film surface, demonstrated by the circular marking at a twin boundary, and indicated by the mirror-like arrangement of the slip traces between the two crystallographic orientations. As already seen in Fig. 3, the \(~\{311\}\) out-of-plane orientation appears to develop due to a constant grain rotation, which is experimentally observed by Feature 8 in Fig. 6 where misorientation gradients are present across the twinned grain. This reorientation seems to also be strain energy driven as well, as reported by Zhang et al. on annealed Cu films on Si substrates.\textsuperscript{47}

Another study dealing with orientation specific damage analysis attributed the higher damage resistance of the \{100\} oriented grains to the lower biaxial stresses (\(\sigma_{111}/\sigma_{100} = 2.26\)) as well as to the lower fraction of applied shear stress, \(\tau\), on a particular slip plane (eight equally active glide systems in \{100\} compared to six in \{111\}).\textsuperscript{20} Considering that after 1000 cycles \(d \geq h_i\) for thicker Cu films (\(h_i = 10, 20 \mu m\)), grain to grain stress interactions are negligible and a single crystal approximation can be used (Schmid’s law).\textsuperscript{22} For such a condition, Mönig et al. computed the corresponding resolved shear stresses for each orientation,\textsuperscript{21} where \(\tau_{212}/\tau_{100} = 1.84\). The \{212\} twin segment has two glide systems with the highest resolved shear stress compared to eight for the \{100\} parent grain which is in agreement with observed roughening in those twin sections [Figs. 6(c) and 6(d), Feature 4]. The experimental stress-temperature response [Fig. 1(e)] of the 20 \(\mu m\) thick film gives further proof to the assumption that the corresponding shear stresses on the eight equally active glide systems are very low. By approximating that the measured film stress \(\sigma_{film}\) corresponds to \(\sigma_{100}\), this would lead to a \(\tau = S_{100} \times \sigma_{100}\) of about \(-24\) MPa and 14 MPa in the heating and cooling stages, respectively.

The site-specific damage investigation presented in Fig. 6 emphasizes that surface damage decreases with increasing film thickness. This can be directly correlated to the large fraction of \{100\} oriented grains which appear to have a higher damage tolerance with respect to thermo-mechanical fatigue. In Fig. 7(a) the root mean squared (RMS) roughness evolution is presented for the three thermally cycled Cu film thicknesses. The initially similar film roughness (88, 79, and 62 nm with increasing \(h_i\))
evolves differently, where the RMS roughness was ranked with respect to the film thickness after 1000 cycles. This result may seem to contradict previous observations illustrated in Fig. 6, where the surface roughness appeared to be inversely proportional on $h_f$. In Fig. 7(b) this contradictory observation regarding the surface roughness can be explained the following way. The representative surface profiles for $h_f = 5, 10$, and $20 \mu m$ reveal that all film surfaces after 1000 cycles have a similar maximum vertical height amplitudes ($\Delta y \sim 1.5 \mu m$), but the frequency of lateral surface roughness (which can be equated to surface damage) appears to increase with decreasing film thickness. This is due to the fact that $R_{\text{RMS}}$ is considered as an amplitude parameter and is only affected by vertical height variations of the film surface. Furthermore, the quadratic dependency of data points accentuates greater height variations providing greater $R_{\text{RMS}}$ values. To show the influence of the increasing fraction of more damage tolerant $\{100\}$ grains with respect to increasing film thickness, 15 AFM profiles were taken after 1000 thermal cycles from each film thickness. The surface profile lengths, extracted by the AFM processing
were normalized with respect to a profile length of 100 μm. This results in a mean surface length of 102.26 ± 0.65 μm, 101.53 ± 0.56 μm, and 101.22 ± 0.52 μm for \( h_f = 5 \), 10, and 20 μm, respectively. To visualize these seemingly similar lateral roughness parameters, a reference roughness function was defined and used in Fig. 7(c), where the obtained surface length \( L_{(f)} \) is defined as

\[
L_{(f)} = \left[ d + \sqrt{\frac{100}{N}} \right]^2 + d \]  

with \( d \) as the chosen roughness height and \( N \) giving the number of roughness intervals. This enables the direct comparison of accumulated surface damage with respect to the film thickness. From the graph it becomes evident that the Cu film with \( h_f = 5 \) μm has the highest accumulated roughness. For the same reference profile length of 100 μm with a chosen roughness height of \( d = 150 \) nm, 15 intervals are required to obtain the experimental mean surface length. In comparison, the thicker films \( h_f = 10 \) and 20 μm result in \( N = 10 \) and 8, respectively, indicating significantly less surface damage with increasing film thickness. The approach of numerically integrating several representative profile lengths over different AFM scans led to a statistical parameter with a physical meaning. Using a chosen reference function and displaying the accumulated damage with similar maximum height differences [see Fig. 7(b)] allow a direct qualitative and quantitative comparison of the film surface roughening (damage) of the three thermo-mechanically cycled film thicknesses [Fig. 7(c)]. The experimental observations from Fig. 6 are confirmed, emphasizing that fatigue damage is inversely proportional to \( h_f \) for thick Cu films (\( h_f \geq 5 \) μm).

IV. CONCLUSIONS AND SUMMARY

In this study, the thermo-mechanical behavior of thick Cu films with thicknesses between 5 and 20 μm was presented. Initial microstructural characteristics of texture and grain size changed as a function of film thickness during 1000 thermo-mechanical cycles. The microstructural evolution during cycling and the corresponding surface damage is significantly different from similar studies on thin Cu films (<5 μm). The following conclusions can be drawn:

(1) Initial microstructural properties indicate that in electrodeposited Cu films, texture transitions toward the \{100\} out-of-plane orientation at film thicknesses ≥ 5 μm occurs.

(2) Pronounced growth of the \{100\} out-of-plane oriented grains during thermal cycling was observed. The grain growth of the \{100\} texture component in
thicker films (10 and 20 μm) agrees with a gradual formation of dislocation substructures.

(3) The thermo-mechanical fatigue damage assessment after thermal cycling (Fig. 6) revealed a transition of orientation independent surface damage (5 μm) to an orientation dependent damage (roughening) for thicker films (10 and 20 μm). A higher damage tolerance was found for the {100} oriented grains because these grains have a lower surface roughness.

(4) The accumulated surface roughness, displayed by the reference function (Fig. 7), indicates that fatigue damage has \( \sim 1/h_1 \) dependency for thicker films (\( \geq 5 \) μm) and is different compared to thin Cu film counterparts (\( \leq 5 \) μm).
